Abstract

The intestine is the primary reservoir of *Candida albicans* that can cause systemic infections in immunocompromised patients. In this reservoir, the fungus exists as a harmless commensal. However, antibiotic treatment can disturb the bacterial microbiota, facilitating fungal overgrowth and favor pathogenicity. Current *in vitro* gut models used to study *C. albicans*' pathogenesis investigate the state where *C. albicans* behaves as a pathogen rather than a commensal. We present a novel *in vitro* gut model where the fungal pathogenicity is reduced to a minimum by increasing the biological complexity. In this model, enterocytes represent the epithelial barrier and goblet cells limit *C. albicans* adhesion and invasion. Significant protection against *C. albicans*-induced necrotic damage was achieved by the introduction of a microbiota of antagonistic lactobacilli. We demonstrated a time-, dose-, and species-dependent protective effect against *C.*

albicans-induced cytotoxicity. This required bacterial growth, which relied on the presence of host cells, but was not dependent on the competition for adhesion sites. *Lactobacillus rhamnosus* reduced hyphal elongation, a key virulence attribute. Furthermore, bacterial-driven shedding of hyphae from the epithelial surface, associated with apoptotic epithelial cells, was identified as a main and novel mechanism of damage protection. However, host cell apoptosis was not the driving mechanism behind shedding. Collectively, we established an in vitro gut model, which can be used to experimentally dissect commensal-like interactions of *C. albicans* with a bacterial microbiota and the host epithelial barrier. We also discovered fungal shedding as a novel mechanism by which bacteria contribute to the protection of epithelial surfaces.
